INTRODUCTION

In 1870, the Swiss chemist *Miescher* discovered inside the nucleus of a cell a giant molecule: **deoxyribonucleic acid**.

In 1953, two biochemists, the American *James Watson* and the English *Francis Crick* show that the structure of the DNA molecule is comparable to that of a spiral staircase; a sort of spiral-shaped double helix.

Deoxyribonucleic acid (**DNA**) is a molecule that encodes the genetic instructions used in the development and functioning of all known living organisms and many viruses. DNA is a nucleic acid; together with proteins and carbohydrates, nucleic acids compose the three major macromolecules essential for all known forms of life.

Most DNA molecules consist of two biopolymer strands coiled around each other to form a double helix. The two DNA strands are known as polynucleotides since they are composed of simpler units called nucleotides. Each nucleotide is composed of a nitrogen-containing nucleobase—either guanine (G), adenine (A), thymine (T), or cytosine (C)—as well as a monosaccharide sugar called deoxyribose and a phosphate group. The nucleotides are joined to one another in a chain by covalent bonds between the sugar of one nucleotide and the phosphate of the next, resulting in an alternating sugar-phosphate backbone. According to base pairing rules (A with T and C with G), hydrogen bonds bind the nitrogenous bases of the two separate polynucleotide strands to make double-stranded DNA.

Picture 1 - DNA structure

DNA is well-suited for biological information storage. The DNA backbone is resistant to cleavage, and both strands of the double-stranded structure store the same biological information. Biological information is **replicated** as the two strands are separated. A significant portion of DNA (more than 98% for humans) is non-coding, meaning that these sections do not serve a function of encoding proteins.

That said, it is easy to understand how DNA is important for life. For this reason, even a small mutation (a change of the nucleotide sequence of the genome of an organism) can be decisive and cause diseases.

In this essay we will discuss a particular case of genomic mutation, the Single Nucleotide Polymorphism.

Single Nucleotide Polymorphism: what is it?

A **Single Nucleotide Polymorphism (SNP)** is a DNA sequence variation occurring commonly within a population (e.g. 1%) in which a Single Nucleotide — A, T, C or G — in the genome differs between members of a biological species or paired chromosomes.

For example, if we have two sequenced DNA fragments from different individuals (see *Picture 2*):

- AAGCCTA
- AAGCTTA

The second one contain a difference in a single nucleotide. In this case we say that there are two alleles. Almost all common SNPs have only two alleles.

Picture 2 – SNP example

The genomic distribution of SNPs is not homogenous; SNPs occur in non-coding regions more frequently than in coding regions.

The main causes of a SNP are:

- 1. natural selection, acting and fixating the allele of the SNP that constitutes the most favorable genetic adaptation
- 2. like genetic recombination
- 3. mutation rate

The different possible types of SNPs

As previously seen, Single Nucleotide Polymorphisms may fall within *coding* sequences of genes, *non-coding* regions of genes, as well as in the *intergenic* regions (regions between genes).

What is a coding?

To understand the difference between SNPs' types, we have to see what a coding is.

The main concept to analyse is the **Genetic Code**: it is the *set of rules* by which information encoded within genetic material (DNA or even mRNA sequences) is *translated* into proteins by living cells.

During the translation, the sequence of nitrogenous bases is treated in groups of three at a time; a group of three nitrogenous bases is called a **codon**. The code defines how codons specify which amino acid will be added next during protein synthesis. Generally, three-nucleotide codon in a nucleic acid sequence specifies a single amino acid. On the other hand, a single amino acid can be specified by more than one codon: this is the key concept that we will need in the following.

To understand better, here is the table that shows, for each amino acid (20 in total + START and STOP), the sequences that can generate it:

Amino acid	Codons
Ala/A	GCT, GCC, GCA, GCG
Arg/R	CGT, CGC, CGA, CGG, AGA, AGG

Asn/N AAT, AAC Asp/D GAT, GAC Cys/C TGT, TGC Gln/Q CAA, CAG Glu/E GAA, GAG Gly/G GGT, GGC, GGA, GGG His/H CAT, CAC Ile/I ATT, ATC, ATA Leu/L TTA, TTG, CTT, CTC, CTA, CTG Lys/K AAA, AAG Met/M ATG Phe/F TTT, TTC Pro/P CCT, CCC, CCA, CCG Ser/S TCT, TCC, TCA, TCG, AGT, AGC Thr/T ACT, ACC, ACA, ACG Trp/W TGG Tyr/Y TAT, TAC Val/V GTT, GTC, GTA, GTG START ATG STOP TAA, TGA, TAG

Table 1 – Inverse genetic code

SNPs in the coding sequences

SNPs that fall in this category can be divided into two subcategories:

- 1. Synonymous
- 2. Nonsynonymous
 - a. Missense
 - b. Nonsense

First ones does not result in a change in the protein sequence, because the "original" sequence and the real sequence of bases both code the same amino acid.

Second ones, instead, change the amino acid sequence of protein. In their turn, they can be of two types: *Missense*, in which a single nucleotide change results in a codon that codes for a different amino acid (that can render the resulting protein non-functional), and *Nonsense*, that results in a premature stop codon, or a nonsense codon and then in a truncated, incomplete, and usually non-functional protein product.

Let us see an example of Missense mutation:

Original DNA code for the amino acid sequence:

Resulting amino acids:

| His |
|-----|-----|-----|-----|-----|-----|-----|

If we had, for example, a replacement of the eleventh nucleotide:

САТ	САТ	САТ	С С Т	САТ	САТ	CAT	
	O /\ .	C /\ .	C 0 1	C /\ \		C /\ \	

Resulting amino acids will be:

His	His	His	Pro	His	His	His
-----	-----	-----	-----	-----	-----	-----

This is, instead, an example of *Nonsense mutation*:

Original DNA code for the amino acid sequence:

A T G A C T	CAC	C G A G C G	CGA	A G C
-------------	-----	-------------	-----	-------

Resulting amino acids:

Mot	Thr	Hic	Λra	۸۱۵	Λra	Sar
iviet	1111	1115	Alg	Ala	Alg	361

If we had, for example, a replacement of the tenth nucleotide:

ATG ACT CAC TGA GCG CGA AGC

Resulting amino acids will be:

Met Thr

Nonsense mutation are jointly responsible for many diseases; they can cause a genetic disease by damaging a gene responsible for a specific protein (for example dystrophin in Duchenne muscular dystrophy).

Examples of diseases in which nonsense mutations are known to be among the causes include:

- Cystic fibrosis
- **Duchenne muscular dystrophy** (dystrophin)
- Beta thalassaemia (β-globin)
- Hurler syndrome

On the other hand, cancer associated Missense mutations can lead to drastic destabilisation of the resulting protein.

SNPs not in coding regions

SNPs that are not in protein-coding regions may still affect:

- 1. gene splicing
- 2. transcription factor binding
- 3. messenger RNA degradation
- 4. ...

Gene expression affected by this type of SNP is referred to as an **eSNP** (*expression SNP*).

How to found SNPs: DNA Sequencing

In order to understand, according to what already said, what a SNP can cause, we must first of all *identify the SNP in the DNA* of the subject under consideration.

There are many possible types of analysis that can be performed (DNA sequencing, capillary electrophoresis, mass spectrometry, electrochemical analysis, ...); in this essay we will look at the most common one: **DNA Sequencing**.

"DNA Sequencing is the process of determining the precise order of nucleotides within a DNA molecule. It includes any method or technology that is used to determine the order of the four bases — adenine, guanine, cytosine, and thymine — in a strand of DNA."

History of DNA Sequencing

Over the years, since the discovery of DNA by *Miescher* in 1870, the problem of DNA sequencing has been addressed in an increasingly thorough (see *Picture 3* in the next page). This also because, in 1940, *Avery* realized, by means of an experiment, that the so-called *transforming principle* (the carrier of genetic information) discovered in 1928 by Griffith was DNA.

Avery's experiment

In short, the Avery experiment was based on the Griffith experiment. Griffith used in his studies the *Streptococcus pneumoniae*. In particular, two of its strains:

- the S strain, which can cause pneumonia in guinea pigs (virulent strain).
- the R strain is not able to cause pneumonia in guinea pigs (avirulent strain).

The main result was this:

injection in mouse of type S bacteria, killed after thermal treatment, and type R live bacteria was able to cause disease and death of the animal. From the tissues of mouse could isolate live bacteria of the S strain.

So, he verified and demonstrated that in a mixture containing either S dead bacteria and R alive bacteria, were to be happened the exchange of some substance (genetic material) that would confer virulence to bacteria R (which were then transformed into S).

The experiment of Avery aimed to determine what this substance was and it was discovered that it would necessarily be DNA.

Picture 3 – History of DNA Sequencing

Progress over the years

The first sequencing occurred in 1953 by Holley.

Since then, the efficiency of sequencing increased exponentially over the years: if in 1953 a person in a year could sequence only one *bp* (base pair), in the seventies we get to more than 1,500, in the nineties to more than 200000 and few years ago, in 2009, to more than 100 billion bps!

Picture 4 – Robert W. Holley

The first full DNA genome to be sequenced was that of bacteriophage ϕ X174 in 1977. Medical Research Council scientists deciphered the complete DNA sequence of the Epstein-Barr virus in 1984, finding it to be 170 thousand base-pairs long.

Sequencing methods

Over the years, many methods have been developed for sequencing the DNA. It goes from *basic methods*, such as the *Maxam-Gilbert sequencing* and *Chain-termination methods*, to advanced methods such as the *Shotgun sequencing* or *PCR Bridge*, to get to the next-generation methods (*Massively Parallel Signature sequencing (MPSS)*, *Polony sequencing*, *454 pyrosequencing*, *Illumina (Solexa) sequencing*, *SOLID sequencing*, *Single Molecule Real Time (SMRT) sequencing*, ...).

Next-Generation Sequencing

Nowadays, thanks to technological progress we pushed even further forward. As can be seen from the following chart, it is possible to sequence **more than 100 million base pairs in about a week** (generating a very high amount of data). This is called the **Next-Generation Sequencing**.

However, the higher the speed of sequencing, the more there is a problem: **interpretation**. It often represents a real bottleneck; a single computer is not able to interpret a sequencing at the same speed of which it is presented to him.

For this reason, usually *cloud computing services* are used. They allow to take advantage of the computing power of multiple computers at the same time, parallelizing the work and thereby reducing the overall time.
